

Analysis of bivariate binomial data: Twin analysis

Klaus Holst & Thomas Scheike

August 12, 2018

Overview

When looking at bivariate binomial data with the aim of learning about the dependence that is present, possibly after correcting for some covariates many models are available.

- Random-effects models logistic regression covered elsewhere (glmer in lme4).

in the mets package you can fit the

- Pairwise odds ratio model
- Bivariate Probit model
 - With random effects
 - Special functionality for polygenic random effects modelling such as ACE, ADE ,AE and so forth.
- Additive gamma random effects model
 - Special functionality for polygenic random effects modelling such as ACE, ADE ,AE and so forth.

Typically it can be hard or impossible to specify random effects models with special structure among the parameters of the random effects. This is possible in our models.

To be concrete about the model structure assume that we have paired binomial data Y_1, Y_2, X_1, X_2 where the responses are Y_1, Y_2 and we have covariates X_1, X_2 .

We start by giving a brief description of these different models. First we for bivariate data one can specify the marginal probability using logistic regression models

$$\text{logit}(P(Y_i = 1|X_i)) = \alpha_i + X_i^T \beta_i = 1, 2.$$

These model can be estimated under working independence ¹.

A typical twin analysis will typically consist of looking at both

- Pairwise odds ratio model
- Bivariate Probit model

The additive gamma can be used for the same as the bivariate probit model but is more restrictive in terms of dependence structure, but is nevertheless still valuable to have also as a check of results of the bivariate probit model.

Biprobit with random effects

For these model we assume that given random effects Z and a covariate vector V_{12} we have independent logistic regression models

$$\text{probit}(P(Y_i = 1|X_i, Z)) = \alpha_i + X_i^T \beta + V_{12}^T Z_i = 1, 2.$$

where Z is a bivariate normal distribution with some covariance Σ . The general covariance structure Σ makes the model very flexible.

We note that

- Parameters β are subject specific
- The Σ will reflect dependence

The more standard link function *logit* rather than the *probit* link is often used and implemented in for example ². The advantage is that one now gets an odds-ratio interpretation of the subject specific effects, but one then needs numerical integration to fit the model.

#We note that

Pairwise odds ratio model

Now the pairwise odds ratio model specifies that given X_1, X_2 the marginal models are

$$\text{logit}(P(Y_i = 1|X_i)) = \alpha_i + X_i^T \beta_i = 1, 2$$

The primary object of interest are the odds ratio between Y_1 and Y_2

$$\gamma_{12} = \frac{P(Y_{ki} = 1, Y_{kj} = 1)P(Y_{ki} = 0, Y_{kj} = 0)}{P(Y_{ki} = 1, Y_{kj} = 0)P(Y_{ki} = 0, Y_{kj} = 1)}$$

given X_{ki}, X_{kj} , and Z_{kji} .

We model the odds ratio with the regression

$$\gamma_{12} = \exp(Z_{12}^T \lambda)$$

Where Z_{12} are some covariates that may influence the odds-ratio between Y_1 and Y_2 and contains the marginal covariates, ³. This odds-ratio is given covariates as well as marginal covariates. The odds-ratio and marginals specify the joint bivariate distribution via the so-called Plackett-distribution.

One way of fitting this model is the ALR algorithm, the alternating logistic regression and this has been described in several papers ⁴. We here simply estimate the parameters in a two stage-procedure ⁴; and

- Estimating the marginal parameters via GEE
- Using marginal estimates, estimate dependence parameters

This gives efficient estimates of the dependence parameters because of orthogonality, but some efficiency may be gained for the marginal parameters by using the full likelihood or iterative fitting such as for the ALR.

The pairwise odds-ratio model is very useful, but one do not have a random effects model.

Additive gamma model

Again we operate under marginal logistic regression models are

$$\text{logit}(P(Y_i = 1|X_i)) = \alpha_i + X_i^T \beta_i = 1, 2$$

First with just one random effect Z we assume that conditional on Z the responses are independent and follow the model

$$\text{logit}(P(Y_i = 1|X_i, Z)) = \exp(-Z \cdot \Psi^{-1}(\lambda_{\bullet}, \lambda_{\bullet}, P(Y_i = 1|X_i)))$$

where Ψ is the laplace transform of Z where we assume that Z is gamma distributed with variance λ_{\bullet}^{-1} and mean 1. In general $\Psi(\lambda_1, \lambda_2)$ is the laplace transform of a Gamma distributed random effect with Z with mean λ_1/λ_2 and variance λ_1/λ_2^2 .

We fit this model by

- Estimating the marginal parameters via GEE
- Using marginal estimates, estimate dependence parameters

To deal with multiple random effects we consider random effects $Z_i, i = 1, \dots, d$ such that Z_i is gamma distributed with mean $\lambda_j/\lambda_{\bullet}$ and variance $\lambda_j/\lambda_{\bullet}^2$, where we define the scalar λ_{\bullet} below.

Now given a cluster-specific design vector V_{12} we assume that

$$V_{12}^T Z$$

is gamma distributed with mean 1 and variance λ_{\bullet}^{-1} such that critically the random effect variance is the same for all clusters. That is

$$\lambda_{\bullet} = V_{12}^T (\lambda_1, \dots, \lambda_d)^T$$

We return to some specific models below, and show how to fit the ACE and AE model using this set-up.

One last option in the model-specification is to specify how the parameters $\lambda_1, \dots, \lambda_d$ are related. We thus can specify a matrix M of dimension $p \times d$ such that

$$(\lambda_1, \dots, \lambda_d)^T = M\theta$$

where θ is d-dimensional. If M is diagonal we have no restrictions on parameters.

This parametrization is obtained with the `var.par=0` option that thus estimates θ .

The DEFAULT parametrization instead estimates the variances of the random effects (`var.par=1`) via the parameters ν

$$M\nu = (\lambda_1/\lambda_{\bullet}^2, \dots, \lambda_d/\lambda_{\bullet}^2)^T$$

The basic modelling assumption is now that given random effects $Z = (Z_1, \dots, Z_d)$ we have independent probabilities

$$\text{logit}(P(Y_i = 1|X_i, Z)) = \exp(-V_{12,i}^T Z \cdot \Psi^{-1}(\lambda_{\bullet}, \lambda_{\bullet}, P(Y_i = 1|X_i))) i = 1, 2$$

We fit this model by

- Estimating the marginal parameters via GEE
- Using marginal estimates, estimate dependence parameters

Even though the model not formally in this formulation allows negative correlation in practice the parameters can be negative and this reflects negative correlation. An advantage is that no numerical integration is needed.

The twin-stutter data

We consider the twin-stutter where for pairs of twins that are either dizygotic or monozygotic we have recorded whether the twins are stuttering ⁵

We here consider MZ and same sex DZ twins.

Looking at the data

```
1 library(mets)
2 data(twinstut)
3 twinstut$bstut <- 1*(twinstut$stutter=="yes")
4 twinsall <- twinstut
5 twinstut <- subset(twinstut, zyg%in%c("mz", "dz"))
6 head(twinstut)

```

Pairwise odds ratio model

We start by fitting an overall dependence OR for both MZ and DZ even though the dependence is expected to be different across zygosity.

The first step is to fit the marginal model adjusting for marginal covariates. We here note that there is a rather strong gender effect in the risk of stuttering.

```
1 margbin <- glm(bstut~factor(sex)+age,data=twinstut,family=
  binomial())
2 summary(margbin)
```

```
Call:
glm(formula = binstut ~ factor(sex) + age, family = binomial(),
    data = twinstut)
```

Now, and more interestingly, we consider an OR that depends on zygosity and note that MZ have a much larger OR than DZ twins. This type of trait is somewhat complicated to interpret, but clearly, one option is that there is a genetic effect, alternatively there might be a stronger environmental effect for MZ twins.

```
1 # design for OR dependence
2 theta.des <- model.matrix( ~-1+factor(zyg),data=twinstut)

Polygenic modelling

We now turn attention to specific polygenic modelling where special random effects are used to specify ACE, AE, ADE models and

so forth. This is very easy with the `bptwin` function. The key parts of the output are the sizes of the genetic component A and the environmental component, and we can compare with the results of the unstructured model above. Also formally we can test if this sub-model is acceptable by a likelihood ratio test.

Additive gamma random effects

Fitting first a model with different size random effects for MZ and DZ. We note that as before in the OR and bivariate probit model the dependence is much stronger for MZ twins. We also test if these are the same by parametrizing the OR model with an intercept. This clearly shows a significant difference.

Polygenic modelling

First setting up the random effects design for the random effects and the the relationship between variance parameters. We see that the genetic random effect has size one for MZ and 0.5 for DZ subjects, that have shared and non-shared genetic components with variance 0.5 such that the total genetic variance is the same for all subjects. The shared environmental effect is the samme for all. Thus two parameters with these bands.

```
1 out <- twin.polygen.design(twinstut,id="tvparr",zygname="
  zyg",zyg="dz",type="ace")
2 head(cbind(out$des.rv,twinstut$tvparnr),10)
3 out$parides
```

```
      MZ DZ DZns1 DZns2 env
1  1  0    0    0  1 2001005
2  1  0    0    0  1 2001005
3  0  1    1    0  1 2001006
8  1  0    0    0  1 2001012
9  1  0    0    0  1 2001012
11 0  1    1    0  1 2001015
12 0  1    1    0  1 2001016
13 0  1    0    1  1 2001016
15 0  1    1    0  1 2001020
18 0  1    1    0  1 2001022

      [,1] [,2]
[1,]  1.0  0
[2,]  0.5  0
[3,]  0.5  0
[4,]  0.5  0
[5,]  0.0  1
```

Now, fitting the ACE model, we see that the variance of the genetic, component, is 1.5 and the environmental variance is -0.5. Thus suggesting that the ACE model does not fit the data. When the random design is given we automatically use the gamma fralty model.

```
1 margbin <- glm(binstut~sex,data=twinstut,family=binomial())
2 bintwin1 <- binomial.twostage(margbin,data=twinstut,
```

```

3     clusters=twinstut$tvparnr,detail=0,theta=c(0.1)/1,var.
        link=0,
4     random.design=out$des.rv,theta.des=out$pardes)
5     summary(bintwin1)

```

For this model we estimate the concordance and casewise concordance as well as the marginal rates of stuttering for females.

```

1     concordance.twin.ace(bintwin1,type="ace")

```

\$MZ

	Estimate	Std.Err	2.5%	97.5%	P-value
concordance	0.0182	0.00147	0.0153	0.0211	2.61e-35
casewise concordance	0.5033	0.03256	0.4395	0.5672	6.49e-54
marginal	0.0362	0.00188	0.0325	0.0399	7.15e-83

\$DZ

	Estimate	Std.Err	2.5%	97.5%	P-value
concordance	0.00235	0.000589	0.0012	0.00351	6.45e-05
casewise concordance	0.06501	0.015836	0.0340	0.09604	4.04e-05
marginal	0.03620	0.001877	0.0325	0.03988	7.15e-83

The E component was not consistent with the fit of the data and we now consider instead the AE model.

```

1     out <- twin.polygen.design(twinstut,id="tvparnr",zygname="
        zyg",zyg="dz",type="ae")
2
3     bintwin <- binomial.twostage(margbin,data=twinstut,
4         clusters=twinstut$tvparnr,detail=0,theta=c(0.1)/1,var.
        link=0,
5         random.design=out$des.rv,theta.des=out$pardes)
6     summary(bintwin)

```
