

LLAMA: Leveraging Learning to Automatically Manage Algorithms

Lars Kotthoff

Abstract

Algorithm portfolio approaches have achieved remarkable improvements over single solvers. However, the implementation of such systems is often highly specialized and specific to the problem domain. This makes it difficult for researchers to explore different techniques for their specific problems. We present LLAMA, a modular and extensible toolkit implemented as an R package that facilitates the exploration of a range of different portfolio techniques on any problem domain. We describe the current capabilities and limitations of the toolkit and illustrate its usage on a set of example SAT problems.

This document corresponds to LLAMA version 0.5.

One-page quick start

So you know about algorithm portfolios and selection and just want to get started. Here we go. In your R shell, type

```
install.packages("llama")  
require(llama)
```

to install and load LLAMA. We're going to assume that you have two input CSV files for your data – one with features and one with times. The rows designate problem instances and the columns feature and solver names. Both files have an "ID" column that allows to link them. Load them into the data structure required by LLAMA as follows.

```
data = input(read.csv("features.csv"),  
             read.csv("times.csv"))
```

You can also use the SAT solver data that comes with LLAMA by running **data(satsolvers)** followed by **data = satsolvers**. Now partition the entire set of instances into training and test sets for cross-validation.

```
folds = trainTest(data)
```

This will give you 10 folds for cross-validation. Now we're ready to train our first model. To do that, we'll need some machine learning algorithms – we're going to use RWeka, which gives us access to everything in Weka. Load RWeka and train a simple classification model that predicts the best algorithm.

```
require(RWeka)  
model = classify(J48, folds)
```

Great! Now let's see how well this model is doing and compare its performance to the virtual best solver (VBS) and the single best solver in terms of average PAR10 score.

```
mean(unlist(parscores(folds, model$predictions)))  
mean(unlist(parscores(data, vbs(data))))  
mean(unlist(parscores(data, singleBest(data))))
```

You can use any other classification algorithms instead of **J48** of course. You can also train regression or cluster models, use different train/test splits or preprocess the data by selecting the most important features. More details in the on-line documentation, or just continue reading for an in-depth tour of LLAMA.

1 Background

Throughout this document, we will assume that the reader is somewhat familiar with algorithm portfolios, algorithm selection, and combinatorial search problems. In this section, some of the background is explained and pointers to additional materials given. Readers familiar with the matter may skip ahead to the next section.

An algorithm portfolio [4, 6] is a collection of state of the art solvers that are all capable of solving the same kind of problem. The rationale of using more than one algorithm or solver for a set of problems is that no single algorithm will be the best for all of these problems. This is known as the no free lunch theorem [19]. If more than one solver is available, we can (at least in theory) choose the best one for each particular problem, thus achieving superior overall performance. The idea of algorithm portfolios was inspired by portfolios in Economics, where a total investment is distributed over multiple securities to minimise the risk.

Many contemporary solvers for artificial intelligence problems have complementing strengths and weaknesses. On a set of problems where one solver exhibits bad performance, another will excel while the picture may be reversed on a different set of problems. Algorithm portfolios exploit this by relating the structure of the problem to solve to the performance of an individual solver or a set of solvers.

SAT is one of the first areas of artificial intelligence that algorithm portfolios and algorithm selection techniques have been applied to, and with great success. The most prominent system is probably SATzilla [22], which has dominated SAT solver competitions when it was introduced. More recent systems include ISAC [9], Hydra [21] and 3S [8].

To use an algorithm portfolio for solving problems, a selection mechanism is required to determine the algorithm to use in the particular case. The concept is closely related to the Algorithm Selection Problem [16], which is concerned with identifying the most suitable algorithm for solving a problem. Usually, some kind of machine learning model is learned to relate the features of a problem instance to the performance of an algorithm or a portfolio. Problem instance features can be anything that describes the instance, for example structural features such as the number of variables in a search problem or probing features such as the progress made after running a benchmark algorithm for a short amount of time on the instance.

There are different ways in which such machine learning models can be used. In the simplest case, a single classification model is trained to predict the best algorithm, given the features of a problem instance. Alternatively, one regression model per algorithm can be trained to predict its performance. The performance predictions can then be used to choose the best algorithm. Another approach is to cluster the problem instances in the training set, determine the best algorithm for each cluster and assign new instances to the closest cluster. These and many more approaches have been used in the literature. LLAMA supports four fundamentally different approaches and a large number of variations of these

involving meta-learning techniques.

A lot more background information can be found in [11] and the overview table of the relevant literature at <http://4c.ucc.ie/~larsko/assurvey/>.

The main drawback of the systems described in the literature is that they are highly tailored and customised for the particular problem domain or even set of problems. On top of that, the implementation may not be available, or may require an obsolete version of Matlab and the respective author’s special environment that makes it work. Even though the high-level approach can usually be applied to other problems, in practice this is almost always very difficult or even impossible. This makes it very difficult to compare different approaches and prototype new ideas especially for researchers who are not algorithm portfolio experts.

This is exactly what LLAMA addresses. Instead of providing a highly-specialised approach that has been tuned and customised to yield high performance on a specific data set, LLAMA is a framework that provides the building blocks for automatic portfolio selectors. It supports the most common approaches to portfolio selection and offers the possibility to combine them into more sophisticated approaches. It furthermore provides an implementation of the infrastructure that is required to build, evaluate and apply algorithm portfolios in practice.

LLAMA is intended to be used by researchers working in the areas of algorithm portfolios, algorithm selection, and algorithm configuration and tuning. It is not particularly user-friendly or easy to use. It does not offer an industrial-strength C++ implementation that you can use in a high-performance portfolio solver. It can be used as a tool for designing such systems, but it will not do all the required work for you.

2 LLAMA for domestic use

As outlined above, the main focus of LLAMA is to provide the user with a framework for the implementation and evaluation of different algorithm selection approaches. It is *not* meant to provide turn-key algorithm portfolio systems that can be used in competitions or similar settings. As such, many of the issues that are highly relevant to algorithm selection systems in competition settings do not have explicit support in LLAMA. Such issues include the fall back to a default solver if feature computation takes too long, the prediction of the time required to compute features or the running of a presolver to take care of the easy problems. LLAMA can certainly be used to address these issues by providing it with suitable input data (see Section 4 for an example), but there is no explicit support for it.

LLAMA is implemented as an R package and can be found at <http://cran.r-project.org/web/packages/llama/>, the development repository is at <https://bitbucket.org/lkotthoff/llama>. One of the main advantages of the R package implementation is that all the functionality available in R can be used to build performance model. This is not limited to the functionality that

is implemented in R itself – there are interfaces to many other packages, such as the well-known Weka machine learning toolkit [5].

The large number of machine learning approaches and algorithms available in R makes it possible to use LLAMA to quickly evaluate a range of different techniques for algorithm selection on given data, such as presented in [13]. Being able to do so is crucial for achieving good performance in practice.

LLAMA provides a number of high-level functions that can be used to create and evaluate algorithm selection models with just a few lines of code. It is helpful to be familiar R and its language, although this document does not assume that you are. You will however need to be somewhat familiar with R to use the more sophisticated functionalities of LLAMA. There are many books on R, e.g. [1].

All of the functions LLAMA provides are documented in R’s online help system, usually with examples of how to use it. To access a help page, simply type `?<name of function>`.

2.1 Installing LLAMA

LLAMA is available on CRAN. On a computer connected to the internet, all you have to do is open an R terminal and type

```
install.packages("llama")
```

Alternatively, you can use the graphical package manager your R distribution provides, or download the package file yourself and install it manually.

Once the package is installed, you can load it by typing `require(llama)`.

2.2 Reading data

Let’s start at the beginning – getting your data into LLAMA. It uses a special data structure that contains, besides the actual performance and feature data, meta data about which algorithm was the best in which case and how to extract feature and performance values. Throughout this document, we will talk about the “performance” of an algorithm – this will usually be its runtime, but can be other things such as the quality of an obtained solution. LLAMA places no restrictions on what “performance” means.

LLAMA’s `input()` function requires a particular data format, but places no restrictions on where the data comes from. Its first argument is a data frame that contains the features for each problem instance. Each row in the data frame designates a different problem instance, each column holds the values for a different feature. The second argument to `input()` is a similar data frame that contains performance information for the algorithms in the portfolio. Both data frames should have a column that holds the ID of the problem instance such that the two data frames can be merged. In fact, LLAMA assumes that any columns that are present in both data frames can be used to merge them.

The third (and optional) argument is a data frame that tells LLAMA whether the run of a particular algorithm on a particular instance was successful or not.

The column names should be the same as for the data frame that holds the algorithm performance values, and there should also be an ID column. Each cell holds a Boolean value designating whether the run was a success or not. The definition of “success” depends on the context; it can for example determine whether an algorithm returned a solution within a certain runtime limit.

If this third argument is specified, an additional way of evaluating the performance of an algorithm selection model is available. There are no other differences; most of the functionality of LLAMA does not require success values. The final (and again optional) argument tells LLAMA whether low performance values are good or bad. It specifies how LLAMA determines the best algorithm, given the performances of the algorithms on an instance. The default behaviour is to assume that smaller values are better (the values give e.g. runtimes). For the opposite behaviour (e.g. quality of solution), specify `minimize=F`.

Assume that your data is in a set of CSV files with the following format.

```
features.csv:
  ID,width,height
0,1.2,3
...more instances...
```

```
performance.csv:
  ID,alg1,alg2
0,2,5
...more instances...
```

```
success.csv:
  ID,alg1,alg2
0,T,F
...more instances...
```

You can load this data into LLAMA as follows.

```
data = input(read.csv("features.csv"),
             read.csv("times.csv"), read.csv("success.csv"))
```

The `input()` function automatically computes all the meta data required by LLAMA – the return value can be used right away. Full details on the returned structure can be found in the on-line documentation.

2.2.1 Example data

LLAMA comes with some example data that you can play around with as a start. The data is runtime data for 19 SAT solvers on 2433 SAT instances [7]. For each instance, 36 features were measured. Success data (i.e. whether an algorithm timed out or not) is also available.

To use this data, type

```
data(satsolvers)
satsolvers
```

If you want to run the following commands with this data, run **data = satsolvers**.

2.3 Slicing and dicing the data

Machine learning models are usually trained and tested on separate data. This is to avoid so-called overfitting, where the model learned is so specific to the data it was trained on that the predictions on anything else are very inaccurate. LLAMA provides functions to split a data set into training and test sets. This is one of the tedious and error-prone steps that researchers have to deal with in practice and that LLAMA aims to make less painful. To split the data into 60% training and 40% test sets, we can run the following command, assuming that your data is available in the **data** variable.

```
split = trainTest(data)
```

The second (optional) argument of the function specifies what fraction of the total data should be used for training. If, instead of a 60-40 split, we want a 70-30 split, all we need to do is run **split = trainTest(data, 0.7)**.

By default, the training and test partitions are *stratified*. That is, the distribution of best-algorithm labels in both partitions is approximately equal. If, for example, solver A is the best on 90% of the instances and solver B on the remaining 10% in the training set, the same will be the case in the test set. To turn off this behaviour, give the additional argument **stratify = F**.

In addition to a simple train-test split, LLAMA also provides a function to create data folds for cross-validation [10], which is in general seen as a more reliable way of evaluating the performance of a learning algorithm. To partition the entire data into 10 stratified folds, run

```
folds = cvFolds(satsolvers)
```

The optional argument **nfolds** allows to specify the number of folds. The default behaviour is again to stratify the folds; this can be turned off in the same way as for **trainTest()**.

2.4 Training and evaluating models

Now that we have both training and test data, we can train an algorithm selection model. To start with, we will train a simple classification model that, given the features of an instance, predicts the algorithm to use. This approach is used for example in [3]. We train a model using the C4.5 decision tree learner [14], J48 in Weka. For this, we load the **RWeka** package and call **classify()** with the name of the machine learning algorithm and the data folds created above.

```
require(RWeka)
model = classify(J48, folds)
```

The call to **classify** trains and tests models on each cross-validation fold. That is, for n folds it trains n models using $n - 1$ partitions for training and the remaining partition for testing. The predictions on these testing partitions are returned along with a prediction function that uses a model that was trained on the *entire* data set. While the cross-validation predictions allow to assess the expected performance of the model, the returned prediction function can be used as a building block for a portfolio system to obtain predictions on new data. For full details on the returned data structure, see the on-line help.

LLAMA provides several functions to evaluate the performance of an approach based on the predictions made. A common performance measure in the SAT community is the PAR (penalized average runtime) score. The score is equal to the time it took the algorithm to solve the instance or, if the algorithm was unable to solve it, a constant factor times the time-out value. Usually, PAR10 is used, meaning that time-outs are penalized by a factor of 10. To compute the average PAR10 score and the total number of solved instances of the approach using the C4.5 decision tree, we can run the following code.

```
parscore = mean(unlist(parscores(folds,
                             model$predictions)))
solved = sum(unlist(successes(folds, model$predictions)))
```

On the example data, we get 5966.314 for the mean PAR10 score and 2034 solved instances. The **parscores** and **successes** evaluation functions, along with their cousin **misclassificationPenalties**, take the data for which the predictions were made as their first argument and the predictions as the second. Optional arguments can be given to specify the penalty factor or the time-out value. By default, the performance value given for an unsuccessful run is assumed to be the time-out.

All evaluation functions return a list of the respective values for the chosen algorithm for each instance. That is, if there are 100 instances in the data, **parscores()** will return a list with 100 values. In this case, the functions even return a list of lists – each top-level list represents a test set and has a list of values for each instance in the test set. This is why we need an additional **unlist** before we are able to compute the average or the sum.

The predictions LLAMA computes are actually not just simple labels. Each “prediction” is a data frame that contains a ranked list of algorithms along with a score value. The number of algorithms in the data frame and the meaning of the score value depend on the model-building function that is used and are explained in the respective on-line help pages. In this case, each data frame will contain only a single algorithm with a score of 1, meaning that this is the algorithm that was predicted by the one classifier. An individual prediction looks like this.

```
model$predictions[[1]][[1]]
  algorithm score
1      clasp     1
```

Computing metrics like the PAR10 score or the number of successes doesn't give us a very good idea of how good the approach actually is. In the algorithm selection community, two common approaches to compare against are the virtual best solver and the single best solver. The virtual best solver assumes that we have a perfect predictor that will always choose the best algorithm for a particular instance. The single best solver is the algorithm in the portfolio that has overall the best performance, i.e. on the largest number of instances in the data set.

LLAMA provides convenience functions that allow to compare to both virtual best and single best solver. They are used in the same way as the predictions from a model are.

```
vbsparscore = mean(unlist(parscores(data, vbs(data))))
vbssolved = sum(unlist(successes(data, vbs(data))))

sbparscore = mean(unlist(parscores(data,
singleBest(data))))
sbsolved = sum(unlist(successes(data, singleBest(data))))
```

Comparing those numbers to the ones from the model that we trained should give us a better idea of its performance. Ideally, the model performance should be better than the one of the single best solver and as close to the virtual best as possible. On the example data, we get a mean PAR10 score of 4631.264 and 2125 solved instances for the VBS, and a mean PAR10 score of 6265.218 and 2014 solved instances for the best single solver. Our classification model definitely improves on the single best solver, but is still quite a bit away from the virtual best.

As mentioned above, the model-building function also returns a prediction function that allows to work with new data. As an example, we will use it to make predictions for the data that we have.

```
model$predictor(subset(data$data, TRUE, data$features))
```

2.5 Other available model types

Instead of using the J48 decision tree inducer, we can use any other classification algorithm. The only change needed is to give the other machine learning algorithm as the first argument.

Building a classifier to predict the best solver for a problem is only one of the approaches to providing a selector for algorithm portfolios. A different approach is used for example in SATzilla [22]. For each solver in the portfolio, a regression model is induced to predict the performance of the solver on a particular problem. Given these predictions, the solver with the best predicted performance is chosen.

LLAMA supports this kind of performance model as well. All we have to do is call a different function and pass in a machine learning algorithm that is able

to learn models to predict numeric quantities as an argument. We use RWeka’s `LinearRegression` as an example.

```
model = regression(LinearRegression, folds)
```

You will notice that running this command takes longer than for the classification example. This is because instead of a single classification model, we now need to train one regression model for each algorithm in the portfolio (if you’re using the example SAT data, 19 different models).

The structure returned by the call is the same as for classification and PAR10 scores and similar are calculated in the same way. We get 5567.844 as mean PAR10 score and 2061 solved instances on the example data – an improvement on our earlier classification model. LLAMA offers a unified interface for all its model-building functions that makes it easy to quickly try different approaches. The difference is that the prediction data frames now contain a row for each algorithm in the portfolio and the score denotes the predicted performance value.

```
model$predictions[[1]][[1]]
```

19	contrasat	-337.4312

Apart from the fact that the regression model is predicting negative runtimes, it appears to work quite well. Negative runtimes do not matter here, as we only use them to rank the algorithms.

By default, the `regression` function assumes that the lowest performance value denotes the best algorithm (like `input`). For the opposite behaviour, if the performance value denotes solution quality for example, pass the `combine = max` argument to `regression`.

The approach used in the most recent version of SATzilla is to train classifiers that predict the better algorithm for each pair of algorithms [23]. This approach

is a hybrid between the single classification model and the regression approach. Its strength comes from the fact that it explicitly considers the relation between two algorithms. It is usually easier to predict which of a pair of algorithms will be better rather than choosing the best from a large set or predicting the performance for each.

The predictions of the individual classifiers are aggregated as votes and the algorithm that has most votes wins. The number of votes for each algorithm can be used to rank all of the portfolio algorithms. This approach is also implemented in LLAMA. The function is called `classifyPairs` and conforms to the usual interface.

```
model = classifyPairs(J48, folds)
```

Running this command on the example SAT data will take quite a long time, as a model for each pair of algorithms needs to be trained. This approach offers great potential for parallelisation though; for more details, see Section 3.4.

On the example data, we get a mean PAR10 score of 5899.071 and 2037 solved instances. The data frame for an individual prediction now looks as follows; the score corresponds to the number of votes.

```
model$predictions[[1]][[1]]
```

	algorithm	score
1	clasp	18
2	march_rw	17
3	mxs	16

14	cryptominisat	5
15	minisat	5
16	minisat_noelim	3
17	glucose	2
18	contrasat	1
19	sat4j	1

A different approach to algorithm selection that is used for example in ISAC [9] is to cluster the training problems and assign the best algorithm to each cluster based on the algorithm performances on the instances in the cluster. Again the only change is to call a different function, this time using RWeka's `XMeans` clustering algorithm.

```
model = cluster(XMeans, folds)
```

The return value corresponds to the usual format. We get a mean PAR10 score of 6695.465 and 1986 solved instances. The prediction data frames contain all portfolio algorithms ranked by performance. The score corresponds to the number of instances in the respective cluster that the respective algorithm was best for.

```

3 Advanced functionality

The previous section gave a glimpse of the core functionality of LLAMA. There is much more functionality beyond that though. All the functions we have used previously take additional arguments that allow them to be customised. The model building functions can work with several machine learning algorithms instead of just one. There are more functions that do exciting things¹.

3.1 Processing the input data

The feature and performance data is often messy – there are missing values, the values of some of the features are the same on all instances, or there is no correlation between feature values and performance. All of this can impact the performance of machine learning models. LLAMA provides functionality to mitigate this.

¹For suitable definitions of “exciting”.

3.1.1 Selecting the most important features

Feature selection is a process by which the features that are relevant for making a particular prediction are identified. If, for example, the values of one feature are the same on all problem instances, the feature does not contribute anything and can be omitted. If on the other hand the values of a feature change as the prediction to be made changes, we definitely want to include this feature.

LLAMA does not offer any actual feature filtering algorithms, just like it does not offer any machine learning algorithms. Rather, it provides the infrastructure to use existing algorithms, which are plentiful in R. As an example, we will use the `FSelector` package, which provides a number of such functions.

Feature filtering in LLAMA is done through the `featureFilter` function. It takes a filtering algorithm and the data frame to use, which has to be in the usual LLAMA format, i.e. what is returned by the `input` function.

```
require(FSelector)  
newdata = featureFilter(cfs, data)
```

The function takes the entire data and runs the feature filtering algorithm to determine the effectiveness of the features with respect to predicting the best algorithm. The features which are retained after filtering will be used in the returned data frame.

This new data can now be used to split into training and test sets and build new models.

```
newfolds = cvFolds(newdata)  
model = classify(J48, newfolds)
```

For the new model with filtered features, we get a mean PAR10 score of 5804.397 and 2044 solved instances – an improvement on our earlier model that used all the features.

3.1.2 Normalising feature values

For some types of models, it may be desirable to normalise the feature values such that they cover the same range over all features. If, for example, we compute the distance between two instances based on the feature values in Euclidean space and the values for a particular feature happen to be 1000 times larger than the other ones, this feature will have the highest impact on the result, even though it may not be important.

LLAMA provides a function that allows to normalise the values of features before they are passed to the model learner. This functionality is different from the feature filtering, which is independent from any further operations. To normalise the feature values, scaling factors need to be computed. These same scaling factors need to be applied when working with new data, i.e. when using the predictor function returned by the model builders.

This is why normalisation is implemented as an optional argument to the model-building functions instead of a standalone functions. The scaling factors

are computed for the training data and saved in the environment such that they can be applied to new data later.

LLAMA currently provides only a single function, **normalize**, for feature value normalisation. This function scales the feature values such that the range for all features is -1 to 1. It is specified through the **pre** argument.

```
model = cluster(XMeans, folds, pre=normalize)
```

We are using the cluster model builder here, as clustering is an application that intrinsically relies on distance measures and is likely to be most affected by large differences in the range of feature values. The feature values can be normalized for all of the other model-building functions in the same way.

On the example data, the mean PAR10 score is 6779.793 and the number of solved instances 1980. In this particular case, normalisation does not seem to improve the performance.

3.1.3 Imputing censored runtimes

Working with empirical performance data is often difficult. If the problem instances are challenging, some of the algorithms may take a very long time to solve them – longer than one is prepared to wait. Usually, algorithms are run with a time-out. That is, if the algorithm did not find a solution after a certain amount of time, it is terminated – its runtime is *censored*. While allows to gather data in more reasonable amounts of time, the result makes machine learning more difficult – if an algorithm timed out, the recorded runtime is not actually the value we want to predict.

One way of addressing this issue is to impute the censored runtimes by learning a machine learning model to predict the runtime on the instances that did not time out and then apply it to the instances that timed out. This process can be repeated to get better models and estimates [17].

This method is implemented in LLAMA in the **imputeCensored** function. Its arguments are a LLAMA data frame, the regression algorithm to model the runtime, and termination conditions. Similar to **featureFilter**, it returns a new data frame with the imputed censored runtimes. Note that, similar to the regression model learner, the imputation function does not check the plausibility of the results – it is possible that the predicted runtimes are less than the time-out!

```
imputed = imputeCensored(data, LinearRegression)
imputedFolds = cvFolds(imputed)
model = regression(LinearRegression, imputedFolds)
```

Note that the performance of a model built on imputed data cannot be compared to models built on the original censored data. All of the instances in the data will be solvable, as there is no time limit any more.

3.2 Portfolio analysis

LLAMA provides the `contributions` function to analyse the contributions a single algorithm makes to a portfolio using techniques from game theory [15]. Running this on the example data distributed with the package gives the following result:

```
sort(contributions(satsolvers))
      clasp  cryptominisat      qutersat
-42499.1089   -8854.7117    740.2909
      glucose      mxc    march_rw
  4678.7110   28069.9128   33521.0780
MPhaseSAT64      precosat      picosat
 44008.3382   54136.9820   64197.8563
glueminisat      lingeling      kontrasat
 67935.5264   76489.3100   78365.7487
      sat4j      riss      cirminisat
 82804.3613   88360.4072   89550.5715
      minisat minisat_noelim      rsat
 99151.8748   108837.5158   180762.3266
      kcnfs
238407.9801
```

The negative numbers designate solvers that do not contribute anything to the portfolio, but causes its performance to decrease. The solver **kcnfs** makes the largest contribution, even though its performance on its own is not particularly good. One of the best overall solvers, **clasp**, actually decreases the performance of the portfolio.

This analysis can be used to determine which algorithms should be included and which ones should be omitted from a portfolio. Note that it is entirely separate from learning a model to make the predictions necessary to choose a solver from the portfolio for a particular problem instance. As such, the theoretical best portfolio might not be the best portfolio to learn models for. To achieve the best performance in practice, the combination of portfolio and algorithm selection model has to be evaluated.

3.3 Meta-learning techniques – ensembles and stacking

One of the main strengths of LLAMA is that meta-learning techniques can be applied to all of the model building functions easily. The idea behind meta-learning is similar to that of algorithm portfolios – instead of relying on a single machine learning algorithm and the model it learns to deliver good predictions, we use several that (hopefully) complement each other.

The two meta-learning concepts implemented in LLAMA are ensembles [2] and stacking [18]. In ensemble learning, multiple machine learning algorithms are run on the same data, learning multiple independent models. The predictions of each model are then combined to determine the overall prediction. In

stacking on the other hand, several machine learning algorithms are layered on top of each other. That is, the first layer learns a model based on the actual data, while the second layer takes the predictions of the first layer as input. The two approaches can be combined – the predictions of an ensemble may be used as the input to a second layer of machine learning that makes the final prediction.

For the `classify` model building functions, both ensemble learning and stacking have been implemented. To use an ensemble, the first argument becomes a list of classification algorithms instead of a single one. To use stacking, that list should have a member named `.combine`.

```
require(e1071)
ensembleModel = classify(list(J48, svm, IBk), folds)
stackedEnsembleModel = classify(list(J48, svm, IBk,
  .combine=J48), folds)
```

We are using the `svm` classifier from the `e1071` package in addition to classifiers from `RWeka` here. The mean PAR10 scores for the ensemble and stacked ensemble models on the example data are 5929.604 and 6602.42, respectively. The numbers of solved instances are 2036 and 1991. Compared to the model based on the single `J48` classifier, ensemble learning improves performance a bit, but stacking does not help.

The prediction data frame for ensemble models has the number of votes for each algorithm as score.

```
ensembleModel$predictions[[1]][[2]]
algorithm score
1          mxc      2
2 cryptominisat    1
```

For regression models, stacking as described in [12] is implemented. Instead of aggregating the predicted performance values by ranking them directly, a classifier is learned to predict, given the performance predictions, the best algorithm. To achieve this, a classification algorithm is given as the `combine` argument and the `stack` argument is set to true.

```
stackedModel = regression(lm, folds, combine=J48,
  stack=T)
```

On the example data, this stacked model achieves a mean PAR10 score of 6257.381 and 2014 solved instances. The performance is worse than for the non-stacked approach used earlier. The reason for this is that the non-stacked combination function, choosing the algorithm with the lowest predicted value, is very hard to learn when considering the performance values independently and not the relation between them.

LLAMA does provide an additional argument for `regression` that allows to make this task easier. The `expand` argument allows to specify a function that, given the performance predictions, can augment the inputs to the classifier. In

this case, we want to add the pairwise absolute differences between the predicted performances of algorithms.

```
stackedModel = regression(lm, folds, combine=J48,
  stack=T,
  expand=function(x) {
    cbind(x, combn(c(1:ncol(x)), 2, function(y) {
      abs(x[,y[1]] - x[,y[2]])
    })))
  })
```

While the function given here may appear cryptic at first, it demonstrates one of the advantages of the implementation of LLAMA as an R package. It allows to use arbitrary R functions to process data. The mean PAR10 score achieved by this model is 6178.127 and the number of solved instances 2020. An improvement over the stacked model without expansion.

For the **classifyPairs** model builder, LLAMA supports meta-learning in the same way as for **regression**. Stacking can be used to provide a classification algorithm in the **combinator** argument that learns to predict the best algorithm, given the votes by the classifiers for pairs of algorithms.

The **cluster** model builder supports meta-learning techniques in the same way as **classify**. More details and examples can be found in the on-line documentation for each of the model builders.

3.4 Parallel execution

Some of the models can take a very long time to train. Most of the operations are independent though and can be parallelised easily. LLAMA uses the **parallelMap** construct from the parallelMap package² to parallelise execution across cross-validation folds. That is, the model for each iteration will be trained and tested in parallel. The **parallelMap** construct provides transparent parallelisation that executes sequentially if no suitable parallel backend is loaded. All the user has to do to enable parallel execution is to load a parallel backend, for example through **parallelStartSocket()**. Libraries used in the spawned processes should be specified through **parallelLibrary**.

```
library(parallelMap)
parallelStartSocket(2) # use 2 CPUs
parallelLibrary("llama", "RWeka")
# LLAMA code
parallelStop()
```

After running these commands, all subsequent calls to LLAMA model building functions will be parallelised across 2 CPUs.

Note that the functions provided by RWeka rely on a Java interface that is not thread-safe. The Weka machine learning algorithms can still be used with

²<https://github.com/berndbischl/parallelMap>

parallel execution though if a backend is used that runs separate processes, such as the sockets backend used above.

4 Case study: SATzilla

Algorithm selection systems often have additional components for which there is no explicit support in LLAMA. This is not necessarily an obstacle though, much additional functionality can be achieved by partitioning the data appropriately and using other functionality that R provides.

This section outlines how to implement SATzilla with the help of LLAMA and R. A full implementation is beyond the scope of this document; instead, this section serves as a guide to researchers wishing to implement such measures. There are several techniques that the various versions of SATzilla use to make algorithm portfolios more performance in practice. We will sketch the implementation of each in turn before putting it all together. The techniques used in this section are described in more details in the SATzilla papers (e.g. [20,22,23]).

The main difference of the implementation sketched here and SATzilla is that we treat all problem instances the same way, without computing any weights that determine the “importance” of the problem instance. In practice, using weights is almost always a good idea.

4.1 Presolver

There are problem instances that can be solved almost instantaneously. For these, the overhead of computing features, running the algorithm selection model, and selecting a solver is too high. Using a portfolio is always going to be slower for these problems. To avoid this issue, we can run a presolver for a short amount of time.

This step is largely independent of training algorithm selection models. We do however need to take into account that the problems that are solved by the presolver within its time limit do not require algorithms to be selected for them, so we should remove them from the data before training the model. This is done easily in R.

```
performanceData = read.csv("performance.csv")
presolveLimit = 1
presolver = "minisat"
newPerformanceData = subset(performanceData,
  performanceData[presolver] > presolveLimit)
data = input(read.csv("features.csv"),
  newPerformanceData)
```

Assuming that our presolver is minisat with a time-out of 1 second, we can filter the data as above before passing it to `input`. There is no need to filter the feature data, as LLAMA will discard any items it cannot match. The resulting LLAMA data frame can be used as usual to train and evaluate models.

4.2 Prediction of satisfiability

SAT solvers often behave differently depending on whether an instance is satisfiable or not. In practice, it can make sense to distinguish between these instances in algorithm portfolios. This requires a larger number of machine learning models. First, we need to be able to predict whether a given instance is satisfiable or not. Second, we need different algorithm selection models for the satisfiable and unsatisfiable cases.

To achieve this, we require additional data on whether an instance is satisfiable or not.

```
performanceData = read.csv("performance.csv")
featureData = read.csv("features.csv")
featureNames = names(featureData)[-1]
satisfiable = read.csv("satisfiable.csv")
satisfiableModel = J48(satisfiable$satisfiable~.,
  data=subset(featureData, T, featureNames))
satisfiableData = input(featureData,
  subset(performanceData, satisfiable$satisfiable))
unsatisfiableData = input(featureData,
  subset(performanceData, !satisfiable$satisfiable))
```

For simplicity, we assume that the first column of the feature file is an ID and that the order of the instances in the feature, performance, and satisfiable files is the same. The `satisfiableModel` can now be used to predict the satisfiability of a new instance, while the LLAMA data frames `satisfiableData` and `unsatisfiableData` can be used to train and evaluate algorithm selection models for the respective parts of the instance space.

4.3 Prediction of feature computation time

Computing the features of an instance is integral to algorithm selection systems. This information can be related to the performance of the algorithms to make predictions as to which algorithm to use in a particular case. However, sometimes just computing the features can take longer than it would take to solve the instance. It is clearly desirable to identify these cases before starting to compute the features.

To achieve this, we can train yet another machine learning model that, given a small and cheaply computable subset of the features, predicts the time required to compute the remaining features. If the time is too high, we simply run a backup solver on the instance. Such instances should not be used in the training and evaluation of the algorithm selection model.

```
featureTimes = read.csv("featureTimes.csv")
reducedFeatureData = read.csv("reducedFeatures.csv")
reducedFeatureNames = names(reducedFeatureData)[-1]
featureTimeModel = LinearRegression(featureTimes$time~.,
  data=subset(reducedFeatureData, T,
```

```

    reducedFeatureNames))
featureTimeLimit = 5
data = subset(subset(read.csv("features.csv"),
    featureTimes$time < featureTimeLimit),
    read.csv("performance.csv"))

```

Similar assumptions as in the section above are made. The LLAMA data frame can now again be used in the usual manner to train algorithm selection models.

4.4 Putting it all together

The techniques outlined in the previous section can now be put together to implement a system similar to SATzilla.

```

performanceData = read.csv("performance.csv")
featureData = read.csv("features.csv")
featureNames = names(featureData)[-1]
reducedFeatureData = read.csv("reducedFeatures.csv")
reducedFeatureNames = names(reducedFeatureData)[-1]
featureTimes = read.csv("featureTimes.csv")
satisfiable = read.csv("satisfiable.csv")

presolveLimit = 1
presolver = "minisat"
featureTimeLimit = 5

toSolve = (performanceData[presolver] >
    presolveLimit)&(featureTimes$time < featureTimeLimit)
featureTimeModel = LinearRegression(featureTimes$time~.,
    data=subset(reducedFeatureData, T,
    reducedFeatureNames))
satisfiableModel = J48(satisfiable$satisfiable~.,
    data=subset(featureData, toSolve, featureNames))

satisfiableData = input(featureData,
    subset(performanceData,
    satisfiable$satisfiable&toSolve))
unsatisfiableData = input(featureData,
    subset(performanceData,
    (!satisfiable$satisfiable)&toSolve))

satisfiableFolds = cvFolds(satisfiableData)
unsatisfiableFolds = cvFolds(unsatisfiableData)
satisfiableModel = classifyPairs(J48, satisfiableFolds)
unsatisfiableModel = classifyPairs(J48,
    unsatisfiableFolds)

```

Let's walk through it step by step. First, we read all the relevant data, as in the individual steps above. Then we set our time limits and the presolver. The data we want to train algorithm selection models for comprises the instances that are not solved by the presolver and for which the feature prediction time is not too long. We save the Boolean mask that encodes these conditions in `toSolve` to be able to filter the data later.

After that, we train our first two models – one to predict the feature computation time and the other to predict whether an instance is satisfiable or not. For the feature computation time, we need to consider all the data, whereas for the prediction of satisfiability we only need the instances that we want algorithm selection models for.

Then, we partition the data based on satisfiability and pass them to `include`, filtering the instances that we do not require algorithm selection for. Finally, we proceed in the usual LLAMA manner by partitioning the data into folds and learning a SATzilla 2012-style pairwise classification model.

To make predictions on new data, we would use the two preliminary models to determine feature computation time and satisfiability and then the `predictor` member of either the `satisfiableModel` or the `unsatisfiableModel`.

Our SATzilla-style solver now looks something like this.

```
function myPortfolioSolver(instance) {
  presolver = "minisat"
  presolveTimeout = 1
  backupsolver = "clasp"
  featureTimeout = 5

  result = runSolver(instance, presolver,
    timeout=presolveTimeout)
  if(!isSolved(result)) {
    simpleFeatures = getSimpleFeatures(instance)
    featureTime = predict(featureTimeMode,
      simpleFeatures)
    if((featureTime > featureTimeLimit) {
      return(runSolver(instance, backupsolver))
    } else {
      features = getFeatures(instance)
      satisfiable = predict(satisfiableModel,
        features)
      if(satisfiable) {
        solver =
          satisfiableModel$predictor(features)
      } else {
        solver =
          unsatisfiableModel$predictor(features)
      }
      return(runSolver(instance, solver))
    }
  }
}
```

```

    }
  } else {
    return(result)
  }
}

```

5 Case study: Visualising the data

Our final case study is going to be a bit more graphic than the previous rather dry sections – we are going to have a look at visualising the data we have been working with. R offers many possibilities for doing so and surveying them all is far beyond the scope of this manual. We only give a flavour of what visualisations can be done.

It is always useful to have a look at the data one will be working with. In our case, there are two main groups of data – the performance values and the features. Let’s have a look at the performance values first. Throughout this section, we will be using the example SAT data, but the same methodology applies to any other data in LLAMA format. As we have a large amount of data to visualise, we are going to use heatmaps.

```

data(satsolvers)
times = subset(satsolvers$data, T,
               satsolvers$performance)
par(mar=c(7,1,3,1))
cols = gray(seq(1, 0, length.out=255))
image(t(as.matrix(times)), axes=F, col=cols)
axis(1, labels=satsolvers$performance, at=seq(0, 1,
1/(length(satsolvers$performance)-1)), las=2)
legend("top", legend=c(min(times), max(times)),
      fill=c("white", "black"), bty="n", inset=-0.12,
      xpd=NA)

```

The graph created by this code is shown in Figure 1. After extracting the performance values (runtimes in this case) from the LLAMA data frame, setting some plot parameters and creating a black and white colour scale, we plot the heatmap, axis, and legend. The map shows the time each solver takes on each instance.

There is a large spread of runtimes in our data, with most instances being solved either instantaneously or timing out. The figure looks accordingly, with most colours being either white or black and very little grey in between. Plotting the log of the runtime is more informative (Figure 2).

```

image(log(t(as.matrix(times))), axes=F, col=cols)
axis(1, labels=satsolvers$performance, at=seq(0, 1,
1/(length(satsolvers$performance)-1)), las=2)

```

Figure 1: Runtimes by solver and instance from almost instantaneous solve (white) to timeout (black).

```
legend("top", legend=c(min(times), max(times)),
      fill=c("white", "black"), bty="n", inset=-0.12,
      xpd=NA)
```

When doing algorithm selection, we are usually more interested in how the performance of a solver compares to the other solvers in the portfolio rather than the absolute value. We can plot the rank of each solver on each instance in a similar fashion to before. The resulting plot is shown in Figure 3.

```
image(apply(times, 1, order), axes=F, col=cols)
axis(1, labels=satsolvers$performance, at=seq(0, 1,
  1/(length(satsolvers$performance)-1)), las=2)
legend("top", legend=c(1,
  length(satsolvers$performance)), fill=c("white",
  "black"), bty="n", inset=-0.12, xpd=NA)
```

Figure 2: Log runtimes by solver and instance from almost instantaneous solve (white) to timeout (black).

The same kind of visual analysis can be applied to the features. This is probably even more important than analysing the performance data, as the features are used to create the models we are going to use for algorithm selection. If the features are bad, the models will not be good either. Let's do the same kind of plot we did for the solvers for the features.

```
features = subset(satsolvers$data, T,
  satsolvers$features)
par(mar=c(10,1,3,1))
image(t(as.matrix(features)), axes=F, col=cols)
axis(1, labels=satsolvers$features, at=seq(0, 1,
  1/(length(satsolvers$features)-1)), las=2)
legend("top", legend=c(min(features), max(features)),
  fill=c("white", "black"), bty="n", inset=-0.12,
  xpd=NA)
```

Figure 3: Solver ranks on each instance from first (white) to last (black).

The resulting plot is shown in Figure 4. The values for four of the features are much higher than the rest. It is hard to see the variance of the feature values for a particular feature over the set of instances because of this.

We get a better plot from the normalised feature values (Figure 5).

```
nFeatures = normalize(features)
par(mar=c(10,1,1,1))
image(t(as.matrix(nFeatures$features)), axes=F, col=cols)
axis(1, labels=satsolvers$features, at=seq(0, 1,
1/(length(satsolvers$features)-1)), las=2)
```

The features for the example data are not very good. For quite a lot of them, there is almost no variation and others have only two different values.

We can apply the same kind of analysis to the prediction results. This allows us to get an idea of what the machine learning algorithms are doing, where they work well and where things could be improved. The following code creates a

Figure 4: Feature values on each instance from lowest (white) to highest (black).

heatmap of the PAR10 scores of a classification model on all instances. We are using the log of the PAR10 scores to get more shades of grey.

```
folds = cvFolds(satsolvers)
model = classify(J48, folds)
scores = unlist(parscores(folds, model$predictions))
par(mar=c(1,1,1,10))
image(log(t(as.matrix(scores))), axes=F, col=cols)
legend("right", legend=quantile(scores),
      fill=gray(seq(1, 0, length.out=5)), bty="n",
      inset=-0.3, xpd=NA)
```

The resulting plot is shown in Figure 6. It gives us some idea of what's going on, but looks more like a bar code than anything else.

The power of heatmaps comes from being able to compare multiple entities. A more useful plot compares the performance of the classification model to the

Figure 5: Normalised feature values on each instance from -1 (white) to 1 (black).

performance of other models. The following code can be used to generate such a plot (Figure 7).

```
folds = cvFolds(satsolvers)
model1 = classify(J48, folds)
model2 = regression(LinearRegression, folds)
model3 = classifyPairs(J48, folds)
model4 = cluster(XMeans, folds)
scores1 = unlist(parscores(folds, model1$predictions))
scores2 = unlist(parscores(folds, model2$predictions))
scores3 = unlist(parscores(folds, model3$predictions))
scores4 = unlist(parscores(folds, model4$predictions))
par(mar=c(10,1,1,1))
names = c(paste("classify", "J48", mean(scores1),
  sep="\n"), paste("regression", "LinearRegression",
```

Figure 6: PAR10 scores for a J48 classification model.

```

mean(scores2), sep="\n"), paste("classifyPairs",
  "J48", mean(scores3), sep="\n"), paste("cluster",
  "XMeans", mean(scores4), sep="\n"))
scores = c(scores1, scores2, scores3, scores4)
image(log(t(matrix(scores, ncol=4))), axes=F, col=cols)
axis(1, labels=names, at=seq(0, 1, 1/(length(names)-1)),
  las=1, tick=F, line=1)
legend("bottom", legend=quantile(scores),
  fill=gray(seq(1, 0, length.out=5)), bty="n",
  inset=-0.4, xpd=NA)

```

This comparison is actually quite insightful. The predictions of the regression model usually incur a higher PAR10 score (overall, the column is darker than the others), but its mean PAR10 score is lower than for the other models. It also shows us that for this specific scenario, there is almost no difference between the single and pairwise classification models.

Figure 7: PAR10 scores for four different models. The number in each label shows the mean PAR10 score across all instances.

As a final example, we will plot the differences in predicted and actual rank for the regression model. The heatmap resulting from the code below is shown in Figure 8.

```
par(mar=c(7,1,1,5))
ranks = apply(sapply(unlist(model2$predictions,
  recursive=F), function(x) { x$algorithm }}, 2,
  function(y) { as.vector(sapply(y, function(z) {
    which(z == satsolvers$performance) }))) })
diffs = apply(times, 1, order)-ranks
cols = c(colorRampPalette(c("red", "white"))(128),
  colorRampPalette(c("white", "blue"))(128))
breaks = c(seq(min(diffs), 0-1/128, length.out=128), 0,
  seq(0+1/128, max(diffs), length.out=128))
image(diffs, axes=F, col=cols, breaks=breaks)
```

Figure 8: Difference between actual and predicted rank for the regression model. Red means that an algorithm was predicted to be worse than it actually was, blue that it was predicted to be better. Predicted and actual rank agree for white.

```
axis(1, labels=satsolvers$performance, at=seq(0, 1,
  1/(length(satsolvers$performance)-1)), las=2)
legend("right", legend=quantile(diffs),
  fill=cols[quantile(1:length(cols))], bty="n",
  inset=-0.15, xpd=NA)
```

The plot is a bit messy, but there are some insights to be gained. Looking at the solvers that perform well overall (e.g. minisat, left column), we can see that they are predominantly red, i.e. most of the time they are predicted to be worse than they actually are. For the solvers that exhibit bad performance (e.g. rsat, right column), we observe that they are predominantly blue, meaning that they are usually predicted to be better than they actually are. This indicates that improvements are to be had by training better machine learning models in this

particular scenario.

The examples above only scratch the surface of the visualisations that are possible in R. While none of the examples shown depends on LLAMA, the data structures it provides facilitate the creation of such plots to some extent.

6 The further domestication of LLAMA

The functionality currently implemented in LLAMA facilitates the exploration of the performance of many different approaches to algorithm selection. It is our intention for LLAMA to develop into a platform that not only facilitates the exploration and comparison of different existing approaches, but also the rapid prototyping of new approaches. The functions it provides take care of the infrastructure required to train and evaluate machine learning models in a scientifically rigorous way. Researchers wishing to improve algorithm portfolio selection do not need to concern themselves with the infrastructure, but can concentrate on the actual research.

LLAMA is still at an early stage of development and bugs may occur. In the end, the responsibility of interpreting and validating the results lies with the user. However, we have used LLAMA for a number of applications, found and fixed a few bugs and are reasonably confident that it will be useful to other people.
